# Chapter 19

# Comments

I found this chapter a bit tough due to the sudden introduction of the node potential  $\phi_t$  in equation 19.24. It really just means that we assign potentials both edges and nodes (unlike what section 19.3 suggests).

# **Exercises**

#### Exercise 1

$$\begin{split} \frac{\partial}{\partial \boldsymbol{\theta}_c} \log Z(\boldsymbol{\theta}) &= \frac{1}{Z(\boldsymbol{\theta})} \frac{\partial}{\partial \boldsymbol{\theta}_c} \left[ \sum_{\mathbf{y}} \exp \left( \boldsymbol{\theta}_c^T \boldsymbol{\phi}_c(\mathbf{y}) \right) \right] \\ &= \sum_{\mathbf{y}} \boldsymbol{\phi}_c(\mathbf{y}) \frac{1}{Z(\boldsymbol{\theta})} \exp \left( \boldsymbol{\theta}_c^T \boldsymbol{\phi}_c(\mathbf{y}) \right) \\ &= \sum_{\mathbf{y}} \boldsymbol{\phi}_c(\mathbf{y}) p(\mathbf{y}|\boldsymbol{\theta}). \end{split}$$

The cost of training an MRF is O(rk(N+c)) = O(r(kN+kc)). Looking at equation 19.41, we see that that we have to compute each feature for each data point per iteration. However, we only have to compute the marginals once per feature.

The cost of training a CRF O(rNk(1+c)) = O(rNkc). The key difference is that the unclamped term is now conditioned on each data point. Thus, we must calculate the marginals N times (assuming that each data point is different). In other words, we must compute the marginal for each feature, iteration, and data point.

# Exercise 4

$$p(x_i = 1 | \mathbf{x}_{\text{nb}_i}) = \frac{p(x_i = 1, \mathbf{x}_{\text{nb}_i} | \boldsymbol{\theta})}{p(x_i = 0, \mathbf{x}_{\text{nb}_i} | \boldsymbol{\theta}) + p(x_i = 1, \mathbf{x}_{\text{nb}_i} | \boldsymbol{\theta})}$$
$$= \frac{e_i^z}{1 + e_i^z}$$
$$= \frac{1}{1 + e^{-z_i}},$$

where

$$z_i = p(x_i = 1, \mathbf{x}_{\text{nb}_i} | \boldsymbol{\theta})$$

$$= \frac{1}{Z(\boldsymbol{\theta})} \exp(h_i) \prod_{j \in \text{nb}_i} \exp(J_{ij} x_j)$$

$$= \exp\left(\log Z(\boldsymbol{\theta}) + h_i + \sum_{j \in \text{nb}_i} J_{ij} x_j\right).$$

If we keep equation 19.125 intact, but switch  $x_i \in \{-1, 1\}$ , then we have

$$p(x_i = 1 | \mathbf{x}_{\text{nb}_i}, \boldsymbol{\theta}) = \frac{z_i^+}{z_i^- + z_i^+}$$

where  $z_i^+$  is the unormalized probability,  $\tilde{p}(x_i = 1 | \mathbf{x}_{\mathrm{nb}_i}, \boldsymbol{\theta})$ . Similarly,  $z_i^- = \tilde{p}(x_i = -1 | \mathbf{x}_{\mathrm{nb}_i}, \boldsymbol{\theta})$ . Since

$$z_i^+ = \exp\left(h_i + \sum_{j \in \text{nb}_i} J_{ij} x_j\right)$$
$$z_i^- = \exp\left(-h_i - \sum_{j \in \text{nb}_i} J_{ij} x_j\right),$$

we can see that  $z_i^- = \frac{1}{z_i^-}$ . Plugging this back into equation 1, we get

$$p(x_i = 1 | \mathbf{x}_{\text{nb}_i}, \boldsymbol{\theta}) = \frac{z_i^+}{z_i^- + z_i^+} = \frac{1}{1 + (z_{\cdot}^-)^2}.$$
